Ln.1 ASEXUAL AND SEXUAL REPRODUCTION IN PLANTS

ONE MARK:

1. Choose the correct statement from the following
   a) Gametes are involved in asexual reproduction
   b) Bacteria reproduce asexually by budding
   c) Conidia formation is a method of sexual reproduction
   d) Yeast reproduce by budding

2. An eminent Indian embryologist is
   a) S.R.Kashyap  b) P.Maheswari  c) M.S. Swaminathan  d) K.C.Mehta

3. Identify the correctly matched pair
   a) Tuber - *Allium cepa*  b) Sucker - *Pistia*
   c) Rhizome - *Musa*  d) Stolon - *Zingiber*

4. Pollen tube was discovered by
   a) J.G.Kolreuter  b) G.B.Amici  c) E.Strasburger  d) E.Hanning

5. Size of pollen grain in *Myosotis*
   a) 10 micrometer  b) 20 micrometer
   c) 200 micrometer  d) 2000 micrometer

6. First cell of male gametophyte in angiosperm is
   a) Microspore  b) megaspore
   c) Nucleus  d) Primary Endosperm Nucleus

7. Match the following
   I) External fertilization  -  i) pollen grain
   II) Androecium  -  ii)ther wall
   III) Male gametophyte  -  iii)alage
   IV) Primary parietal layer  -  iv)stamens
   a)I-ii;II-iii;III-ii;IV-iii  b)I-iii;II-iv;III-i;IV-ii
   c)I-iii;II-iii;III-i;IV-ii  d)I-ii;II-ii;III-ii;IV-ii

8. Arrange the layers of anther wall from locus to periphery
   a) Epidermis,middle layers, tapetum, endothecium
   b) Tapetum, middle layers, epidermis, endothecium
   c) Endothecium, epidermis, middle layers, tapetum
   d) Tapetum, middle layers, endothecium, epidermis

9. Identify the incorrect pair
   a) sporopollenin - exine of pollen grain
   b) tapetum – nutritive tissue for developing microspores
   c) Nucellus – nutritive tissue for developing embryo
   d) obturator – directs the pollen tube into micropyle

10. Assertion : Sporopollenin preserves pollen in fossil deposits
    Reason : Sporopollenin is resistant to physical and biological decomposition
     a) assertion is true; reason is true
     b) assertion is false; reason is true
     c) Both Assertion and reason are not true
     d) Both Assertion and reason are true.

11. Choose the correct statement(s) about tenuinucellate ovule
     a) Sporogenous cell is hypodermal
     b) Ovules have fairly large nucellus
     c) sporogenous cell is epidermal
     d) Ovules have single layer of nucellus tissue

12. Which of the following represent megagametophyte
     a) Ovule  b)Embryo sac  c)Nucellus  d)Endosperm

13. In *Haplopappus gracilis*, number of chromosomes in cells of nucellus is 4. What will be the chromosome number in Primary endosperm cell?
     a)8  b)12  c)6  d)2

14. Transmitting tissue is found in
     a) Micropylar region of ovule  b) Pollen tube wall
     c) Stylar region of gynoecium  d) Integument

15. The scar left by funiculus in the seed is
     a)tegmen  b)radicle  c)epicotyl  d)hilum

16. A Plant called X possesses small flower with reduced perianth and versatile anther. The probable agent for pollination would be
     a)water  b)air  c)beetles  d)butterflies

17. Consider the following statement(s)
     i) In Protandrous flowers pistil matures earlier
     ii) In Protogynous flowers pistil matures earlier
     iii) Herkogamy is noticed in unisexual flowers
     iv) Distyly is present in *Primula"
     a) i and ii are correct  b) ii and iv are correct
     c) ii and iii are correct  d) i and iv are correct
18. Coelorriza is found in
   a) Paddy   b) Bean   c) Pea   d) Tridax

19. Parthenocarpic fruits lack
   a) Endocarp   b) Epicarp   c) Mesocarp   d) seed

20. In majority of plants pollen is liberated at
   a) 1 celled stage   b) 2 celled stage
   c) 3 celled stage   d) 4 celled stage

2 MARKS AND 3 MARKS:

1. Reproduction:
   One of the essential features of all living things on the earth is reproduction. Reproduction is a vital process for the existence of a species and it also brings suitable changes through variation in the offspring for their survival on earth.

2. Importance of plant reproduction:
   Plant reproduction is important not only for its own survival but also for the continuation and existence of all other organisms since the latter directly or indirectly depend on plants. Reproduction also plays an important role in evolution.

3. Types of reproduction - 2

4. Asexual reproduction:
   The reproduction method which helps to perpetuate its own species without the involvement of gametes is referred to as asexual reproduction.

5. Methods of asexual reproduction in lower plants, fungi & animals -
   1. formation of Conidia (Aspergillus and Penicillium)
   2. Budding (Yeast and Hydra)
   3. Fragmentation (Spirogyra)
   4. production of Gemma (Marchantia)
   5. Regeneration (Planaria)
   6. Binary fission (Bacteria)

6. Clones:
   The individual formed by asexual method is morphologically and genetically identical and are called clones.

7. Method of asexual reproduction in higher plants:
   Higher plants also reproduce asexually by Vegetative reproduction

8. Vegetative reproduction:
   A form of asexual reproduction in plants in which multicellular structures become detached from the parent and develop into new individuals that are genetically identical to parent.

9. Types of Vegetative reproduction – 2
   1. Natural method   2. Artificial method

10. Natural vegetative reproduction:
   Natural vegetative reproduction is a form of asexual reproduction in which a bud grows and develops into a new plant. The buds may be formed in organs such as root, stem and leaf. At some stage, the new plant gets detached from the parent plant and starts to develop into a new plant.

11. Reproductive propagules or diasporas:
   Some of the organs involved in the vegetative reproduction also serve as the organs of storage and perennation. The unit of reproductive structure used in propagation is called reproductive propagules or diaspores.

12. Types of organs help in vegetative reproduction - 3
   1. root   2. Stem   3. Leaf

13. Vegetative reproduction in root:
   The roots of some plants develop vegetative or adventitious buds on them. Example Murraya, Dalbergia and Millingtonia. Some tuberous adventitious roots apart from developing buds also store food. Example Ipomea batatas and Dahlia. Roots possessing buds become detached from the parent plant and grow into independent plant under suitable condition.

14. Vegetative reproduction in stem:
   Rhizome (Musa paradisiaca, Zingiber officinale and Curcuma longa);
   corm (Amorphophallus and Colocasia); tuber (Solanum tuberosum); bulb (Allium cepa and Lilium) runner (Centella asiatica); stolon (Mentha, and Fragaria); offset (Pistia, and Eichhornia); sucker (Chrysanthemum) and bulbi (Dioscorea and Agave).

   The axillary buds from the nodes of rhizome and eyes of tuber give rise to new plants.
15. Modern methods:
Now-a-days, technology is being used for propagation to produce large number of plants in a short period of time. Such methods are said to be modern methods.

16. Vegetative reproduction in leaf:
In some plants adventitious buds are developed on their leaves. When they are detached from the parent plant they grow into new individual plants. Examples: *Bryophyllum, Scilla,* and *Begonia.* In *Bryophyllum,* the leaf is succulent and notched on its margin. Adventitious buds develop at these notches and are called **epiphyllous buds.** They develop into new plants forming a root system and become independent plants when the leaf gets decayed. Scilla is a bulbous plant and grows in sandy soils. The foliage leaves are long and narrow and epiphyllous buds develop at their tips. These buds develop into new plants when they touch the soil.

17. Epiphyllous buds:
In *Bryophyllum,* the leaf is succulent and notched on its margin. Adventitious buds develop at these notches and are called **epiphyllous buds.**

18. Advantages of natural vegetative reproduction:
- Only one parent is required for propagation.
- The new individual plants produced are genetically identical.
- In some plants, this enables to spread rapidly. Example: *Spinifex*
- Horticulturists and farmers utilize these organs of natural vegetative reproduction for cultivation and to harvest plants in large scale.

19. Disadvantage of natural vegetative reproduction
- New plants produced have no genetic variation.

20. Artificial vegetative reproduction / artificial propagation:
Apart from the natural methods of vegetative reproduction, a number of methods are used in agriculture and horticulture to propagate plants from their parts. Such methods are said to be artificial propagation.

21. Conventional methods:
Some of the artificial propagation methods have been used by man for a long time and are called **conventional methods.**

22. Types of conventional propagation methods – 3
1. cutting
2. Grafting
3. layering

23. Cutting:
It is the method of producing a new plant by cutting the plant parts such as root, stem and leaf from the parent plant. The cut part is placed in a suitable medium for growth. It produces root and grows into a new plant.

24. Types of cutting - 3
1. Root cutting (*Malus*)
2. stem cutting (*Hibiscus, Bougainvillea* and *Moringa*)
3. Leaf cutting (*Begonia, Bryophyllum*).

25. Grafting:
In this, parts of two different plants are joined so that they continue to grow as one plant. Of the two plants, the plant which is in contact with the soil is called **stock** and the plant used for grafting is called **scion.** Examples are Citrus, Mango and Apple.

26. Types of grafting - 5
There are different types of grafting based on the method of uniting the scion and stock. They are bud grafting, approach grafting, tongue grafting, crown grafting and wedge grafting.

27. Bud grafting:
A T- shaped incision is made in the stock and the bark is lifted. The scion bud with little wood is placed in the incision beneath the bark and properly bandaged with a tape.

28. Approach grafting:
In this method both the scion and stock remain rooted. The stock is grown in a pot and it is brought close to the scion. Both of them should have the same thickness. A small slice is cut from both and the cut surfaces are brought near and tied together and held by a tape. After 1-4 weeks the tip of the stock and base of the scion are cut off and detached and grown in a separate pot.

29. Tongue grafting:
A scion and stock having the same thickness is cut obliquely and the scion is fit into the stock and bound with a tape.

30. Crown grafting:
When the stock is large in size scions are cut into wedge shape and are inserted on the slits or clefts of the stock and fixed in position using graft wax.

31. Wedge grafting:
In this method a slit is made in the stock or the bark is cut. A twig of scion is inserted and tightly bound so that the cambium of the two is joined.
32. Layering:
In this method, the stem of a parent plant is allowed to develop roots while still intact. When the root develops, the rooted part is cut and planted to grow as a new plant. Examples: \textit{Ixora} and \textit{Jasminum}.

33. Types of layering – 2
1. Mound layering
2. Air layering

34. Mound layering:
This method is applied for the plants having flexible branches. The lower branch with leaves is bent to the ground and part of the stem is buried in the soil and tip of the branch is exposed above the soil. After the roots emerge from the part of the stem buried in the soil, a cut is made in parent plant so that the buried part grow into a new plant.

35. Air layering:
In this method the stem is girdled at nodal region and hormones are applied to this region which promotes rooting. This portion is covered with damp or moist soil using a polythene sheet. Roots emerge in these branches after 2-4 months. Such branches are removed from the parent plant and grown in a separate pot or ground.

36. Advantages of conventional methods
\begin{itemize}
  \item The plants produced are genetically uniform.
  \item Many plants can be produced quickly by this method.
  \item Some plants produce little or no seeds; in others, the seeds produced do not germinate. In such cases, plants can be produced in a short period by this method.
  \item Some plants can be propagated more economically by vegetative propagation.
\end{itemize}
Example: \textit{Solanum tuberosum}.
\begin{itemize}
  \item Two different plants with desirable characters such as disease resistant and high yield can be grafted and grown as a new plant with the same desirable characters.
\end{itemize}

37. Disadvantages of conventional methods
\begin{itemize}
  \item Use of virus infected plants as parents produces viral infected new plants.
  \item Vegetative structures used for propagation are bulky and so they are difficult to handle and store.
\end{itemize}

38. Totipotency:
The genetic ability of a plant cell to produce the entire plant under suitable conditions is said to be totipotency.

39. Uses of totipotency:
This characteristic feature of a cell is utilized in horticulture, forestry and industries to propagate plants.

40. Tissue culture:
The growth of plant tissue in special culture medium under suitable controlled conditions is known as \textit{tissue culture}.

41. Micropropagation:
The regeneration of a whole plant from single cell, tissue or small pieces of vegetative structures through tissue culture is called \textit{micropropagation}.

42. Advantages of modern methods
\begin{itemize}
  \item Plants with desired characteristics can be multiplied rapidly in a short duration.
  \item Plants produced are genetically identical.
  \item Tissue culture can be carried out in any season to produce plants.
  \item Plants which do not produce viable seeds and seeds that are difficult to germinate can be propagated by tissue culture.
  \item Rare and \textit{endangered} plants can be propagated.
  \item Disease free plants can be produced by \textit{meristem culture}.
  \item Cells can be genetically modified and transformed using tissue culture.
\end{itemize}

43. Disadvantages of modern methods
\begin{itemize}
  \item It is labour intensive and requires skilled workers.
  \item Sterile condition must be maintained which adds to the cost.
  \item Since the clones are genetically identical, the entire crop is susceptible to new diseases or changes in environmental conditions will wipe out the species.
  \item Sometimes, \textit{callus} undergoes genetical changes which are undesirable for commercial use.
\end{itemize}

44. Types of gametic fusion -3
\begin{itemize}
  \item 1. Isogamy
  \item 2. Anisogamy
  \item 3. Oogamy
\end{itemize}

45. Sexual Reproduction
Sexual reproduction involves the production and fusion of male and female gametes.
The former is called gametogenesis and the latter is the process of fertilization. Algal & bryophytes reproduce by the production of gametes which may be motile or non motile depending upon the species.
In algae external fertilization takes place whereas in higher plants internal fertilization occurs.

46. Flower:
For a Morphologist, a flower is a highly condensed shoot meant for reproduction.
A flower possesses four whorls- Calyx, Corolla, Androecium and Gynoecium. Androecium and Gynoecium are essential organs.
47. The stages of process or changes involved in sexual reproduction of higher plants – 3

1. Pre-fertilization  
2. Fertilization  
3. Post fertilization changes.

48. Pre-fertilization structure and events

The hormonal and structural changes in plant lead to the differentiation and development of floral primordium.

49. Differentiation:

Animals and plants produced by sexual reproduction begin life as a single cell, a fertilised egg or zygote. These cells must divide by mitosis to produce a multicellular organism.

50. Floral primordium:

A floral primordium is a group of cells or a tissue in an angiosperm or a flowering plant which gives rise to a flower. It is a tissue or a colony of cells that trigger the formation of an organ before its formation.

51. Male Reproductive part – Androecium:

Androecium is made up of stamens. Each stamen possesses an anther and a filament. Anther bears pollen grains which represent the male gametophyte.

52. Difference between periclinal division & anticlinal division:

<table>
<thead>
<tr>
<th>Sl.no</th>
<th>periclinal division:</th>
<th>anticlinal division:</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>division occur parallel to the tissue/organ surface. As a result, we get rows of cells stacked one over the other.</td>
<td>Division occur at right angles to the tissue/organ surface.</td>
</tr>
</tbody>
</table>

53. Microsporogenesis:

The stages involved in the formation of haploid microspores from diploid microspore mother cell through meiosis is called Microsporogenesis.

54. sporogenous tissue:

The primary sporogeneous cells directly, or may undergo a few mitotic divisions to form sporogenous tissue.

55. pollinium:

In some plants, all the microspores in a microsporangium remain held together called pollinium. Example: Calotropis.

56. corpusculum:

Pollinia are attached to a clamp or clip like sticky structure called corpusculum.

57. retinaculum:

The filamentous or thread like part arising from each pollinium is called retinaculum.

58. Translator:

The whole structure looks like inverted letter 'Y' and is called translator.
59. Functions of Tapetum:

- It supplies nutrition to the developing microspores.
- It contributes sporopollenin through **ubisch bodies** thus plays an important role in pollen wall formation.
- The pollenkitt material is contributed by tapetal cells and is later transferred to the pollen surface.
- Exine proteins responsible for ‘rejection reaction’ of the stigma are present in the cavities of the exine. These proteins are derived from tapetal cells.

60. Anther Cavity:

The anther cavity is filled with microspores in young stages or with pollen grains at maturity. The meiotic division of microspore mother cells gives rise to microspores which are haploid in nature.

61. Connective tissue:

It is the column of sterile tissue surrounded by the anther lobe. It possesses vascular tissues. It also contributes to the inner tapetum.

62. Difference between Intine & Exine:

<table>
<thead>
<tr>
<th>Sl.no</th>
<th>Intine</th>
<th>Exine</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>Intine is thin, uniform and is made up of pectin, hemicellulose, cellulose and callose together with proteins.</td>
<td>Exine is thick and is made up of cellulose, sporopollenin and pollenkitt. The exine is not uniform and is thin at certain areas.</td>
</tr>
</tbody>
</table>

63. Sculpturing pattern of pollen grains:

1. rod like  2. grooved  3. warty  4. punctuate

64. Shape of pollen grain:

1. globose  2. ellipsoid  3. Fusiform  4. lobed  5. angular  6. crescent shaped

65. Size of pollen grain:

The size of the pollen varies from 10 micrometers in *Myosotis* to 200 micrometers in members of the family Cucurbitaceae and Nyctaginaceae.

66. Types of microspore nucleus - 2

1. Vegetative nucleus  2. Generative nucleus

67. Number of ovules in ovary:

- One - paddy, wheat & mango
- Many – papaya, water melon & orchids

68. Integuments:

- Outer covering layer. It protects an ovule.
- Ovule with one integment – **unitegmic**, ovule with two integuments – **bitegmic**.

69. Hilum:

The point of attachment of funicle to the body of the ovule is known as **hilum**.

70. raphae:

In an inverted ovule, the funicle is adnate to the body of the ovule forming a ridge called **raphé**.

71. Chalaza:

The basal region of the body of the ovule where the nucellus, the integument and the funicle meet or merge is called as **chalaza**.

72. Embryo sac:

There is a large, oval, sac-like structure in the nucellus toward the micropylar end called embryo sac or female gametophyte.

73. Endothecium:

In some species (unitegmic tenuinucellate) the inner layer of the integument may become specialized to perform the nutritive function for the embryo sac and is called as **endothelium** or **integumentary tapetum** (Example: Asteraceae).

74. Types of ovule (based on the position of the sporogenous cell) – 2

1. Tenuinucellate ovule  2. Crassinucellate ovule

75. Difference between Tenuinucellate & Crassinucellate:

<table>
<thead>
<tr>
<th>Sl.no</th>
<th>Tenuinucellate</th>
<th>Crassinucellate</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>If the sporogenous cell is hypodermal with a single layer of nucellar tissue around it is called <strong>tenuinucellate</strong> type. Normally tenuinucellate ovules have very small nucellus.</td>
<td>Ovules with subhypodermal sporogenous cell is called <strong>crassinucellate</strong> type. Normally these ovules have fairly large nucellus.</td>
</tr>
</tbody>
</table>
76. Difference between hypostase & epistase:

<table>
<thead>
<tr>
<th>S.no</th>
<th>hypostase</th>
<th>epistase</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>Group of cells found at the base of the ovule between the chalaza and embryo sac is called <strong>hypostase</strong></td>
<td>the thick-walled cells found above the micropylar end above the embryo sac is called <strong>epistase</strong></td>
</tr>
</tbody>
</table>

77. Types of ovule – 6

1. Orthotropous
2. Anatropous
3. Hemianatropous
4. Campylotropous
5. Amphitropous
6. Circinotropous

78. Orthotropous:

In this type of ovule, the micropyle is at the distal end and the micropyle, the funicle and the chalaza lie in one straight vertical line. Examples: Piperaceae, Polygonaceae

79. Anatropous:

The body of the ovule becomes completely inverted so that the micropyle and funiculus come to lie very close to each other. This is the common type of ovules found in dicots and monocots.

80. Hemianatropous:

In this, the body of the ovule is placed transversely and at right angles to the funicle. Example: Primulaceae.

81. Campylotropous:

The body of the ovule at the micropylar end is curved and more or less bean shaped. The embryo sac is slightly curved. All the three, hilum, micropyle and chalaza are adjacent to one another, with the micropyle oriented towards the placenta. Example: Leguminosae

82. Amphitropous:

The distance between hilum and chalaza is less. The curvature of the ovule leads to horse-shoe shaped nucellus. Example: some Alismataceae.

83. Circinotropous:

Funiculus is very long and surrounds the ovule. Example: Cactaceae

84. megasporogenesis:

The process of development of a megaspore from a megaspore mother cell is called **megasporogenesis**.

85. Types of embryo sac (based on no.of megaspore) - 3

1. monosporic
2. Bisporic
3. Tetrasporic

86. monosporic:

Of the four megaspores formed, usually the chalazal one is functional and other three megaspores degenerate. The functional megaspore forms the female gametophyte or embryo sac. This type of development is called **monosporic** development (Example: *Polygonum*).

87. Bisporic:

Of the four megaspores formed if two are involved in Embryo sac formation the development is called **bisporic** (Example: *Allium*).

88. Tetrasporic:

If all the four megaspores are involved in Embryo sac formation the development is called **tetr sporic** (Example: *Peperomia*).

88. Pollination:

Pollination is a wonderful mechanism which provides food, shelter etc., for the pollinating animals. Many plants are pollinated by a particular animal species and the flowers are modified accordingly and thus there exists a co-evolution between plants and animals.

89. Pollination in Maize (*Zea mays)*:

The maize is monoecious and unisexual. The male inflorescence (tassel) is borne terminally and female inflorescence (cob) laterally at lower levels. Maize pollens are large and heavy and cannot be carried by light breeze. However, the mild wind shakes the male inflorescence to release the pollen which falls vertically below. The female inflorescence has long stigma (silk) measuring upto 23 cm in length, which projects beyond leaves. The pollens drop from the tassel is caught by the stigma.

90. Cheiropoterophily:

Pollination carried out by bats is called cheiropoterophily. Some of the common cheiropoterophilous plants are *Kigelia africana*, *Adansonia digitata*, etc.,

Malacophily: Pollination by slugs and snails is called malacophily. Some plants of Araceae are pollinated by snails. Water snails crawling among *Lemma* pollinate them.
91. Entomophily:
Pollination by insects is called Entomophily. Pollination by ant is called myrmecophily. Insects that are well adapted to bring pollination are bees, moths, butterflies, flies, wasps and beetles. Of the insects, bees are the main flower visitors and dominant pollinators. Insects are chief pollinating agents and majority of angiosperms are adapted for insect pollination. It is the most common type of pollination.

92. pollination mechanism:
Some of the other interesting pollination mechanisms found in plants are a) Trap mechanism (Aristolochia); Pit fall mechanism (Arum); Clip or translator mechanism (Asclepiadaceae) and Piston mechanism (Papilionaceae).

93. Advantages of self-pollination:
• Pollination is almost certain in bisexual flowers.
• When the members of the species are uncommon and are separated by large distances, the plant has to depend on self-pollination.
• If all the chances of cross-pollination fails, self-pollination will take place and prevent the extinction of the species.

94. Disadvantages of self-pollination:
• Continuous self-pollination, generation after generation results in weaker progeny.
• Chances of producing new species and varieties are meager.

95. Advantages of cross-pollination:
• It always results in bringing out much healthier offsprings.
• Germination capacity is much higher.
• New varieties may be produced.
• The adaptability of the plants to their environment is better.

96. Disadvantages of cross-pollination:
• Depend on external agencies for the pollination and the process is uncertain.
• Various devices have to be adopted to attract pollinating agents.

97. Significance of Pollination
• Pollination is a pre-requisite for the process of fertilisation. Fertilisation helps in the formation of fruits and seeds.
• It brings the male and female gametes closer for the process of fertilisation.
• Cross-pollination introduces variations in plants due to the mixing up of different genes. These variations help the plants to adapt to the environment and results in speciation.

98. Fertilization
The fusion of male and female gamete is called fertilization. Fertilization in angiosperms is double fertilization type.

99. Post Fertilization structure and events
After fertilization, several changes take place in the floral parts up to the formation of the seed (Figure 1.20). The events after fertilization (endosperm, embryo development, formation of seed, fruits) are called post fertilization changes.

100. Functions of endosperm:
• It is the nutritive tissue for the developing embryo.
• In majority of angiosperms, the zygote divides only after the development of endosperm.
• Endosperm regulates the precise mode of embryo development.

101. Development of Dicot embryo:
The Stages involved in the development of Dicot embryo (Capsella bursapastoris – Onagrad or crucifer type) is given in Figure 1.22. The embryo develops at micropylar end of embryo sac. The zygote undergoes transverse division to form upper or terminal cell and lower or basal cell. Further divisions in the zygote during the development lead to the formation of embryo. Embryo undergoes globular, heart shaped stages before reaching a mature stage. The mature embryo has a radicle, two cotyledons and a plumule.

102. Seed
The fertilized ovule is called seed and possesses an embryo, endosperm and a protective coat. Seeds may be endospermous (wheat, maize, barley and sunflower) or non endospermous. (Bean, Mango, Orchids and cucurbits).

103. Significance of parthenocarpy:
• The seedless fruits have great significance in horticulture.
• The seedless fruits have great commercial importance.
• Seedless fruits are useful for the preparation of jams, jellies, sauces, fruit drinks etc.
• High proportion of edible part is available in parthenocarpic fruits due to the absence of seeds.
EXTRA POINTS:

1. **Apospory**: The process of embryo sac formation from diploid cells of nucellus as a result of mitosis.

2. **Budding**: A method of asexual reproduction where small outgrowth (Bud) from a parent cell are produced.

3. **Callus**: Undifferentiated mass of cells obtained through tissue culture.

4. **Clone**: Genetically identical individuals.

5. **Endothecium**: A single layer of hygroscopic, radially elongated cells found below the epidermis of anther which helps in dehiscence of anther.

6. **Fertilization**: The act of fusion of male and female gametophytes.

7. **Grafting**: Conventional method of reproduction where stock and scion are joined to produce new plant.

8. **Horticulture**: Branch of plant science that deals with the art of growing fruits, vegetables, flowers and ornamental plants.

9. **Nucellus**: The diploid tissue found on the inner part of ovule next to the integuments.

10. **Pollen**: A sticky covering found on the surface of the pollen that helps to attract insects.

11. **Regeneration**: Ability of organisms to replace or restore the lost parts.

12. **Sporopollenin**: Pollen wall material derived from carotenoids and is resistant to physical and biological decomposition.

13. **Tapetum**: Nutritive tissue for the developing sporogenous tissue.

14. **Transmitting tissue**: A single layer of glandular canal cells lining the inner part of style.

5 marks:

1. **Development of anther**:

A very young anther develops as a homogenous mass of cells surrounded by an epidermis. During its development, the anther assumes a four-lobed structure. In each lobe, a row or a few rows of hypodermal cells becomes enlarged with conspicuous nuclei. This functions as archesporium. The archesporial cells divide by periclinal divisions to form primary parietal cells towards the epidermis and primary sporogenous cells towards the inner side of the anther. The primary parietal cells undergo a series of periclinal and anticlinal division and form 2-5 layers of anther walls composed of endothecium, middle layers and tapetum, from periphery to centre.

2. **Microsporogenesis**:

The stages involved in the formation of haploid microspores from diploid microspore mother cell through meiosis is called **Microsporogenesis**. The primary sporogenous cells directly, or may undergo a few mitotic divisions to form sporogenous tissue. The last generation of sporogenous tissue functions as microspore mother cells. Each microspore mother cell divides meiotically to form a tetrad of four haploid microspores (microspore tetrad). Microspores soon separate from one another and remain free in the anther locule and develop into pollen grains. In some plants, all the microspores in a microsporangium remain held together called pollinium. Example: *Calotropis*. Pollinia are attached to a clamp or clip like sticky structure called corpusculum. The filamentous or thread like part arising from each pollinium is called retinaculum. The whole structure looks like inverted letter ‘Y’ and is called translator.

3. **Development of Male gametophyte**:

The microspore is the first cell of the male gametophyte and is haploid. The development of male gametophyte takes place while they are still in the microsporangium. The nucleus of the microspore divides to form a vegetative and a generative nucleus. A wall is laid around the generative nucleus resulting in the formation of two unequal cells, a large irregular nucleus bearing with abundant food reserve called vegetative cell and a small generative cell. At this 2 celled stage, the pollens are liberated from the anther. In some plants the generative cell again undergoes a division to form two male gametes. In these plants, the pollen is liberated at 3 celled stage. In 60% of the angiosperms pollen is liberated in 2 celled stage. Further, the growth of the male gametophyte occurs only if the pollen reaches the right stigma. The pollen on reaching the stigma absorbs moisture and swells. The intine grows as pollen tube through the germ pore. In case the pollen is liberated at 2 celled stage the generative cell divides in the pollen into 2 male cells (sperms) after reaching the stigma or in the pollen tube before reaching the embryo sac.
4. Female reproductive part – Gynoecium

The gynoecium represents the female reproductive part of the flower. The word gynoecium represents one or more pistils of a flower. The word pistil refers to the ovary, style and stigma. A pistil is derived from a carpel. The word ovary represents the part that contains the ovules. The stigma serves as a landing platform for pollen grains. The style is an elongated slender part beneath the stigma. The basal swollen part of the pistil is the ovary. The ovules are present inside the ovary cavity (locule) on the placenta. Gynoecium (carpel) arises as a small papillate outgrowth of meristematic tissue from the growing tip of the floral primordium. It grows actively and soon gets differentiated into ovary, style and stigma. The ovules or megasporangia arise from the placenta. The number of ovules in an ovary may be one (paddy, wheat and mango) or many (papaya, water melon and orchids).

5. Types of Ovules:

The ovules are classified into six main types based on the orientation, form and position of the microyle with respect to funicle and chalaza. Most important ovule types are orthotropous, anatropous, hemianatropous and campylotropous.

Orthotropous: In this type of ovule, the micropyle is at the distal end and the micropyyle, the funicle and the chalaza lie in one straight vertical line. Examples: Piperaceae, Polygonaceae.

Anatropous: The body of the ovule becomes completely inverted so that the micropyle and funiculus come to lie very close to each other. This is the common type of ovules found in dicots and monocots.

Hemianatropous: In this, the body of the ovule is placed transversely at right angles to the funicle. Example: Primulaceae.

Campylotropous: The body of the ovule at the micropylar end is curved and more or less bean shaped. The embryo sac is slightly curved. All the three, hilum, micropyyle and chalaza are adjacent to one another, with the micropyyle oriented towards the placenta. Example: Leguminosae.

Amphitropous: The distance between hilum and chalaza is less. The curvature of the ovule leads to horse-shoe shaped nucellus. Example: some Alismataceae.

Circinotropous: Funiculus is very long and surrounds the ovule. Example: Cactaceae

6. Megasporogenesis:

The process of development of a megaspore from a megaspore mother cell is called megasporogenesis. As the ovule develops, a single hypodermal cell in the nucellus becomes enlarged and functions as archesporium. In some plants, the archesporial cell may directly function as megasporocyte mother cell. In others, it may undergo a transverse division to form outer primary parietal cell and inner primary sporegenous cell. The parietal cell may remain undivided or divide by few periclinal and anticlinal divisions to embed the primary sporegenous cell deep into the nucellus. The primary sporegenous cell functions as a megasporocyte mother cell. The megasporocyte mother cell undergoes meiotic division to form four haploid megaspores. Based on the number of megaspores that develop into the Embryo sac, we have three basic types of development: monosporic, bisporic and tetrasporic. The megaspores are usually arranged in a linear tetrad. Of the four megaspores formed, usually the chalazal one is functional and other three megaspores degenerate. The functional megaspore forms the female gametophyte or embryo sac. This type of development is called monosporic development (Example: Polygonum). Of the four megaspores formed if two are involved in Embryo sac formation the development is called bisporic (Example: Allium). If all the four megaspores are involved in Embryo sac formation the development is called tetrasporic (Example: Peperomia). An ovule generally has a single embryo sac.

7. Development of Monosporic embryo sac.

The functional megaspore is the first cell of the embryo sac or female gametophyte. The megaspore elongates along micropyyle- chalazal axis. The nucleus undergoes a mitotic division. Wall formation does not follow the nuclear division. A large central vacuole now appears between the two daughter nuclei. The vacuole expands and pushes the nuclei towards the opposite poles of the embryo sac. Both the nuclei divide twice mitotically, forming four nuclei at each pole. At this stage all the eight nuclei are present in a common cytoplasm (free nuclear division). After the last nuclear division the cell undergoes appreciable elongation, assuming a sac-like appearance. This is followed by cellular organization of the embryo sac. Of the four nuclei at the micropylar end of the embryo sac, three organize into an egg apparatus, the fourth one is left free in the cytoplasm of the central cell as the upper polar nucleus. Three nuclei of the chalazal end form three antipodal cells whereas the fourth one functions as the lower polar nucleus. Depending on the plant the 2 polar nuclei may remain free or may fuse to form a secondary nucleus (central cell). The egg apparatus is made up of a central egg cell and two synergids, one on each side of the egg cell. Synergids secrete chemotropic substances that help to attract the pollen tube. The special cellular thickening called filiform apparatus of synergids help in the absorption, conduction of nutrients from the nucellus to embryo sac. It also guides the pollen tube into the egg. Thus, a 7 celled with 8 nucleated embryo sac is formed.
8. The significance of the process of pollination.

The pollen grains produced in the anther will germinate only when they reach the stigma of the pistil. The reproductive organs, stamens and pistil of the flower are spatially separated, a mechanism which is essential for pollen grains to reach the stigma is needed. This process of transfer of pollen grains from the anther to a stigma of a flower is called pollination.

Pollination is a characteristic feature of spermatophyte (Gymnosperms and Angiosperms). Pollination in gymnosperms is said to be direct as the pollens are deposited directly on the exposed ovules, whereas in angiosperms it is said to be indirect, as the pollens are deposited on the stigma of the pistil. In majority of angiosperms, the flower opens and exposes its mature anthers and stigma for pollination. Such flowers are called chasmogamous and the phenomenon is chasmogamy. In other plants, pollination occurs without opening and exposing their sex organs. Such flowers are called cleistogamous and the phenomenon is cleistogamy. Based upon the flower on which the pollen of a flower reaches, the pollination is classified into two kinds, namely, self-pollination (Autogamy) and cross-pollination (Allogamy).

9. Self-pollination or Autogamy

(Greek Auto = self, gamos = marriage): According to a majority of Botanists, the transfer of pollen on the stigma of the same flower is called self-pollination or Autogamy. Self-pollination is possible only in those plants which bear bisexual flowers. In order to promote self-pollination the flowers of the plants have several adaptations or mechanisms. They are:

1. Cleistogamy: In cleistogamy (Greek Kleisto = closed. Gamos = marriage) flowers never open and expose the reproductive organs and thus the pollination is carried out within the closed flower. Commelina, Viola, Oxalis are some examples for cleistogamous flowers. In Commelina benghalensis, two types of flowers are produced-aerial and underground flowers. The aerial flowers are brightly coloured, chasmogamous and insect pollinated. The underground flowers are borne on the subterranean branches of the rhizome that are dull, cleistogamous and self-pollinated and are not depended on pollinators for pollination.

2. Homogamy: When the stamens and stigma of a flower mature at the same time it is said to be homogamy. It favours self-pollination to occur. Example: Mirabilis jalapa, Catharanthus roseus

3. Incomplete dichogamy: In dichogamous flowers the stamen and stigma of a flower mature at different time. Sometimes, the time of maturation of these essential organs overlap so that it becomes favourable for self-pollination.

10. Agents of pollination:

Pollination is effected by many agents like wind, water, insects etc. On the basis of the agents that bring about pollination, the mode of pollination is divided into abiotic and biotic. The latter type is used by majority of plants.

Abiotic agents 1. Anemophily - pollination by Wind 2. Hydrophily - pollination by Water

Biotic agents
3. Zoophily
Zoophily refers to pollination through animals and pollination through insects is called Entomophily.

1. Anemophily: Pollination by wind. The wind pollinated flowers are called anemophilous. The wind pollinated plants are generally situated in wind exposed regions. Anemophily is a chance event. Therefore, the pollen may not reach the target flower effectively and are wasted during the transit from one flower to another. The common examples of wind pollinated flowers are - grasses, sugarcane, bamboo, coconut, palm, maize etc.,

11. Anemophilous plants have the following characteristic features:

- The flowers are produced in pendulous, catkin-like or spike inflorescence.
- The axis of inflorescence elongates so that the flowers are brought well above the leaves.
- The perianth is absent or highly reduced.
- The flowers are small, inconspicuous, colourless, not scented, do not secrete nectar.
- The stamens are numerous, filaments are long, exerted and versatile.
- Anthers produce enormous quantities of pollen grains compared to number of ovules available for pollination. They are minute, light and dry so that they can be carried to long distances by wind.
- In some plants anthers burst violently and release the pollen into the air. Example: Urtica.
- Stigmas are comparatively large, protruding, sometimes branched and feathery, adapted to catch the pollen grains. Generally single ovule is present.
- Plant produces flowers before the new leaves appear, so the pollen can be carried without hindrance of leaves.

12. The ornithophilous flowers have the following characteristic features:

- The flowers are usually large in size.
- The flowers are tubular, cup shaped or urn-shaped.
- The flowers are brightly coloured, red, scarlet, pink, orange, blue and yellow which attracts the birds.
- The flowers are scentless and produce nectar in large quantities. Pollen and nectar form the floral rewards for the birds visiting the flowers.
- The floral parts are tough and leathery to withstand the powerful impact of the visitors.
13. Pollination in *Salvia* (Lever mechanism):

The flower of *Salvia* is adapted for Beepollination. The flower is petandrous and the corolla is bilabiate with 2 stamens. A lever mechanism helps in pollination. Each anther has an upper fertile lobe and lower sterile lobe which is separated by a long connective which helps the anthers to swing freely. When a bee visits a flower, it sits on the lower lip which acts as a platform. It enters the flower to suck the nectar by pushing its head into the corolla. During the entry of the bee into the flower the body strikes against the sterile end of the connective. This makes the fertile part of the stamen to descend and strike at the back of the bee. The pollen gets deposited on the back of the bee. When it visits another flower, the pollen gets rubbed against the stigma and completes the act of pollination in *Salvia*.

14. Double fertilization and triple fusion:

S.G. Nawaschin and L.Guignard in 1898 and 1899, observed in *Lilium* and *Fritillaria* that both the male gametes released from a male gametophyte are involved in the fertilization. They fertilize two different components of the embryo sac. Since both the male gametes are involved in fertilization, the phenomenon is called double fertilization and is unique to angiosperms. One of the male gametes fuses with the egg nucleus (syngamy) to form Zygote.

The second gamete migrates to the central cell where it fuses with the polar nuclei or their fusion product, the secondary nucleus and forms the primary endosperm nucleus (PEN). Since this involves the fusion of three nuclei, this phenomenon is called triple fusion. This act results in endosperm formation which forms the nutritive tissue for the embryo.

15. Structure of a *Cicer* seed as an example for Dicot seed

The mature seeds are attached to the fruit wall by a stalk called funiculus. The funiculus disappears leaving a scar called hilum. Below the hilum a small pore called micropyle is present. It facilitates entry of oxygen and water into the seeds during germination. Each seed has a thick outer covering called seed coat. The seed coat is developed from integuments of the ovule. The outer coat is called testa and is hard whereas the inner coat is thin, membranous and is called tegmen. In pea plant the tegmen and testa are fused. Two cotyledons laterally attached to the embryonic axis are present. It stores the food materials in pea whereas in other seeds like castor the tegmen and testa are fused. Two cotyledons laterally attached to the embryonic axis are developed from integuments of the ovule. The outer coat is called **micropyle** (PEN) and their fusion product, the secondary nucleus and forms the primary endosperm nucleus (PEN). Since this involves the fusion of three nuclei, this phenomenon is called triple fusion. This act results in endosperm formation which forms the nutritive tissue for the embryo.

16. Structure of *Oryza* seed as an example for Monocot seed

The seed of paddy is one seeded and is called Caryopsis. Each seed remains enclosed by a brownish husk which consists of glumes arranged in two rows. The seed coat is a brownish, membranous layer closely adhered to the grain. Endosperm forms the bulk of the grain and is the storage tissue. It is separated from embryo by a definite layer called **epithelium**. The embryo is small and consists of one shield-shaped cotyledon known as scutellum present towards lateral side of embryonal axis. A shortaxis with plumule and radicle protected by the root cap is present. The plumule is surrounded by a protective sheath called coleoptile. The radicle including root cap is also covered by a protective sheath called coleorhiza. The scutellum supplies the growing embryo with food material absorbed from the endosperm with the help of the epithelium.

17. Apomixis

Reproduction involving fertilization in flowering plants is called amphimixis and wherever reproduction does not involve union of male and female gametes is called apomixis.

The term Apomixis was introduced by Winkler in the year 1908. It is defined as the substitution of the usual sexual system (Amphimixis) by a form of reproduction which does not involve meiosis and syngamy.

Maheswari (1950) classified Apomixis into two types - Recurrent and Non recurrent

Recurrent apomixis: It includes vegetative reproduction and agamospermy

Non recurrent apomixis: Haploid embryo sac developed after meiosis, develops into a embryo without fertilization.

18. Vegetative reproduction:

Plants propagate by any part other than seeds

Bulbils – *Fritillaria imperialis*; Bulbs – *Allium*; Runner – *Mentha arvensis*; Sucker - *Chrysanthemum*

Agamospermy: It refers to processes by which Embryos are formed by eliminating meiosis and syngamy.

Adventive embryony

An Embryo arises directly from the diploid sporophytic cells either from nucellus or integument. It is also called sporophytic budding because gametophytic phase is completely absent. Adventive embryos are found in *Citrus* and *Mangifera*

Diplospory (Generative apospory): A diploid embryo sac is formed from megaspore mother cell without a regular meiotic division Examples. *Eupatorium* and *Aerva*.

Apospory: Megaspore mother cell undergoes the normal meiosis and four megaspores formed gradually disappear. A nucellar cell becomes activated and develops into a diploid embryo sac. This type of apospory is also called somatic apospory. Examples *Hieracium* and *Parthenium*.

20. Polyembryony

Occurrence of more than one embryo in a seed is called polyembryony. The first case of polyembryony was reported in certain oranges by Anton van Leeuwenhoek in the year 1719. Polyembryony is divided into four categories based on its origin.

a. Cleavage polyembryony (Example: Orchids)

b. Formation of embryo by cells of the Embryo sac other than egg

(Synergids – Aristolochia; antipodals – Ulmus and endosperm – Balanophora)

c. Development of more than one Embryo sac within the same ovule.

(Derivatives of same MMC, derivatives of two or more MMC – Casuarina)

d. Activation of some sporophytic cells of the ovule

(Nucellus/ integuments-Citrus and Syzygium).

Practical applications

The seedlings formed from the nucellar tissue in Citrus are found better clones for Orchards. Embryos derived through polyembryony are found virus free.

21. Parthenocarpy

As mentioned earlier, the ovary becomes the fruit and the ovule becomes the seed after fertilization. However, in a number of cases, fruit-like structures may develop from the ovary without the act of fertilization. Such fruits are called parthenocarpic fruits. Invariably they will not have true seeds. Many commercial fruits are made seedless. Examples: Banana, Grapes and Papaya.

Nitsch in 1963 classified the parthenocarpy into following types:

Genetic Parthenocarpy:
Parthenocarpy arises due to hybridization or mutation. Examples: Citrus, Cucurbita.

Environmental Parthenocarpy:
Environmental conditions like frost, fog, low temperature, high temperature etc., induce Parthenocarpy. For example, low temperature for 3-19 hours induces parthenocarpy in Pear.

Chemically induced Parthenocarpy:
Application of growth promoting substances like Auxins and Gibberellins induces parthenocarpy.

22. The characteristic features of entomophilous flowers are as follows:

- Flowers are generally large or if small they are aggregated in dense inflorescence. Example: Asteraceae flowers.
- Flowers are brightly coloured. The adjacent parts of the flowers may also be brightly coloured to attract insects. For example in Poinsettia and Bougainvillea, the bracts become coloured.
- Flowers are scented and produce nectar.
- Flowers in which there is no secretion of nectar, the pollen is either consumed as food or used in building up of its hive by the honeybees. Pollen and nectar are the floral rewards for the visitors.
- Flowers pollinated by flies and beetles produce foul odour to attract pollinators.
- In some flowers juicy cells are present which are pierced and the contents are sucked by the insects.
23. Endosperm

The primary endosperm nucleus (PEN) divides immediately after fertilization but before the zygote starts to divide, into an endosperm. The primary endosperm nucleus is the result of triple fusion (two polar nuclei and one sperm nucleus) and thus has 3n number of chromosomes. It is a nutritive tissue and regulatory structure that nourishes the developing embryo. Depending upon the mode of development three types of endosperm are recognized in angiosperms. They are nuclear endosperm, cellular endosperm and helobial endosperm.

**Nuclear endosperm**: Primary Endosperm Nucleus undergoes several mitotic divisions without cell wall formation thus a free nuclear condition exists in the endosperm. Examples: *Coccinia, Capsella* and *Arachis*

**Cellular endosperm**: Primary endosperm nucleus divides into 2 nuclei and it is immediately followed by wall formation. Subsequent divisions also follow cell wall formation. Examples: *Adoxa, Helianthus* and *Scoparia*

**Helobial endosperm**: Primary Endosperm Nucleus moves towards base of embryo sac and divides into two nuclei. Cell wall formation takes place leading to the formation of a large micropylar and small chalazal chamber. The nucleus of the micropylar chamber undergoes several free nuclear division whereas that of chalazal chamber may or may not divide. Examples: *Hydrilla* and *Vallisneria*.

The endosperm may either be completely consumed by the developing embryo or it may persist in the mature seeds. Those seeds without endosperms are called non-endospermous or ex-albuminous seeds. Examples: *Pea, Groundnut* and *Beans*. Those seeds with endosperms are called endospermous or albuminous seeds. The endosperms in these seeds supply nutrition to the embryo during seed germination. Examples: *Paddy, Coconut* and *Castor*.

**Ruminante endosperm**: The endosperm with irregularity and unevenness in its surface forms ruminante endosperm. Examples: *Areca catechu, Passiflora* and *Myristica*.

24. Structure of ovule(Megasporangium):

Ovule is also called megasporangium and is protected by one or two covering called **integuments**. A mature ovule consists of a stalk and a body. The stalk or the **funiculus** (also called funicule) is present at the base and it attaches the ovule to the placenta. The point of attachment of funicule to the body of the ovule is known as **hilum**. It represents the junction between ovule and funicule. In an inverted ovule, the funicule is adnate to the body of the ovule forming a ridge called **raphe**. The body of the ovule is made up of a central mass of parenchymatous tissue called **nucellus** which has large reserve food materials. The nucellus is enveloped by one or two protective coverings called **integuments**. Integument encloses the nucellus completely except at the top where it is free and forms a pore called micropyle. The ovule with one or two integuments are said to be **unitegmic or bitemic** ovules respectively. The basal region of the body of the ovule where the nucellus, the integument and the funicule meet or merge is called as **chalaza**. The ovule is large, oval, sac-like structure in the nucellus toward the micropylar end called **embryo sac** or female gametophyte. It develops from the functional megasporangium formed within the nucellus. In some species (unitegmic tenuinucellate) the inner layer of the integument may become specialized to perform the nutritive function for the embryo sac and is called as **endothelium** or **integumentary tapetum** (Example: Asteraceae). There are two types of ovule based on the position of the sporogenous cell. If the sporogenous cell is hypodermal with a single layer of nucellar tissue around it is called **tenuinucellate** type. Normally tenuinucellate ovules have very small nucellus. Ovules with subhypodermal sporogenous cell is called **crassinucellate** type. Normally these ovules have fairly large nucellus. Group of cells found at the base of the ovule between the chalaza and embryo sac is called **hypostase** and the thick -walled cells found above the micropylar end above the embryo sac is called **epipostase**.

25. T.S of mature anther:

Transverse section of mature anther reveals the presence of anther cavity surrounded by an anther wall. It is bilobed, each lobe having 2 theca (ditecous). A typical anther is tetrasporangiate.

The mature anther wall consists of the following layers **a. Epidermis b. Endothecium c. Middle layers d. Tapetum.**

- **a. Epidermis**: It is single layered and protective in function. The cells undergo repeated anticlinal divisions to cope up with the rapidly enlarging internal tissues.

- **b. Endothecium**: It is generally a single layer of radially elongated cells found below the epidermis. The inner tangential wall develops bands (sometimes radial walls also) of cellulose (sometimes also slightly lignified). The cells are **hygroscopic**. In the anthers of aquatic plants, saprophytes, cleistogamous flowers and extreme parasites endochelical differentiation is absent. The cells along the junction of the two sporangia of an anther lobe lack these thickening. This region is called **stomium**. This region along with the hygroscopic nature of endothecium helps in the dehiscence of anther at maturity.

- **c. Middle layers**: Two to three layers of cells next to endothecium constitute middle layers. They are generally ephemeral. They disintegrate or get crushed during maturity.

- **d. Tapetum**: It is the innermost layer of anther wall and attains its maximum development at the tetrad stage of microsporogenesis. It is derived partly from the peripheral wall layer and partly from the connective tissue of the anther lining the anther locule. Thus, the tapetum is dual in origin. It nourishes the developing sporogenous tissue, microspore mother cells and microspores. The cells of the tapetum may remain uninucleate or may contain more than one nucleus or the nucleus may become polyploid. It also contributes to the wall materials, sporopollenin, pollenkitt, tryphine and number of proteins that control incompatibility reaction. Tapetum also controls the fertility or sterility of the microspores or pollen grains. There are two types of tapetum based on its behaviour. They are: **Secretory tapetum** (parietal/glandular/ cellular): The tapetum retains the original position and cellular integrity and nourishes the developing microspores. **Invasive tapetum** (periplasmodial): The cells loose their inner tangential and radial walls and the proplastid of all tapetal cells coalesce to form a periplasmodium.

26. Microspores and pollen grains:

Microspores are the immediate product of meiosis of the microspore mother cell whereas the pollen grain is derived from the microspore. The microspores have protoplast surrounded by a wall which is yet to be fully developed. The pollen protoplast consists of dense cytoplasm with a centrally located nucleus. The wall is differentiated into two layers, namely, inner layer called intine and outer layer called exine. Intine is thin, uniform and is made up of pectin, hemicellulose, cellulose and callose together with proteins. Exine is thick and is made up of cellulose, sporopollenin and pollenkitt. The exine is not uniform and is thin at certain areas. When these thin areas are small and round it is called germ pores or when elongated it is called furrows. It is associated with germination of pollen grains. The sporopollenin is generally absent in germ pores. The surface of the exine is either smooth or sculptured in various patterns (rod like, grooved, warty, punctate etc.) The sculpturing pattern is used in the plant identification and classification.

Shape of a pollen grain varies from species to species. It may be globose, ellipsoid, fusiform, lobed, angular or crescent shaped. The size of the pollen varies from 10 micrometers in *Myosotis* to 200 micrometers in members of the family Cucurbitaceae and Nyctaginaceae.

The wall material sporopollenin is contributed by both pollen cytoplasm and tapetum. It is derived from carotenoids. It is resistant to physical and biological decomposition. It helps to withstand high temperature and is resistant to strong acid, alkali and enzyme action. Hence, it preserves the pollen for long periods in fossil deposits, and it also protects pollen during its journey from anther to stigma.

Pollenkitt is contributed by the tapetum and coloured yellow or orange and is chiefly made of carotenoids or flavonoids. It is an oily layer forming a thick viscous coating over pollen surface. It attracts insects and protects damage from UV radiation.

27. Cross pollination

It refers to the transfer of pollens on the stigma of another flower. The cross-pollination is of two types:

i. Geitonogamy: When the pollen deposits on another flower of the same individual plant, it is said to be geitonogamy. It usually occurs in plants which show monoecious condition. It is functionally cross-pollination but is similar to autogamy because the pollen comes from same plant.

ii. Xenogamy: When the pollen (genetically different) deposits on another flower of a different plant of the same species, it is called as xenogamy.

Contrivances of cross-pollination

The flowers of the plants have also several mechanisms that promote cross-pollination which are also called contrivances of cross-pollination or outbreeding devices. It includes the following.

1. Dicliny or Unisexuality

When the flowers are unisexual only cross-pollination is possible. There are two types.

i. Monoeious: Male and female flowers on the same plant. Coconut, Bitter gourd. In plants like castor and maize, autogamy is prevented but geitonogamy takes place.

ii. Dioecious: Male and female flowers on different plants. *Borassus, Carica papaya* and date palm. Here both autogamy and geitonogamy are prevented.

2. Monoiclly or Bisexuality

Flowers are bisexual and the special adaptation of the flowers prevents self-pollination.

i. Dichogamy: In bisexual flowers anthers and stigmas mature at different times, thus checking self-pollination. It is of two types.

a. Protandry: The stamens mature earlier than the stigmas of the flowers. Examples: Helianthus, Clerodendrum (Figure 1.12 a).

b. Protogyny: The stigmas mature earlier than the stamens of the flower. Examples: *Scrophularia nodosa* and *Aristolochia bracteata*.

ii. Herkogamy: In bisexual fl owers the essential organs, the stamens and stigmas, are arranged in such a way that self-pollination becomes impossible. For example in *Gloriosa superba*, the style is reflexed away from the stamens and in *Hibiscus* the stigmas project far above the stamens.

iii. Heterostyly: Some plants produce two or three different forms of fl owers that are different in their length of stamens and style. Pollination will take place only between organs of the same length. (Figure 1.14) a. Distyly: The plant produces two forms of fl owers, Pin or long style, long stigmatic papillae, short stamens and small pollen grains; Th rum-eyed or short style, small stigmatic papillae, long stamens and large pollen grains. Example: *Primula* (Figure 1.14a). Th e stigma of the Th rum-eyed fl owers and the anther of the pin lie in same level to bring out pollination. Similarly the anther of Th rum-eyed and stigma of pin ones is found in same height. Th is helps in effective pollination.

b. Tristyly: Th e plant produces three kinds of fl owers, with respect to the length of the style and stamens. Here, the pollen from fl owers of one type can pollinate only the other two types but not their own type. Example: *Lythrum* (Figure 1.14b).

iv. Self sterility/Self-incompatibility: In some plants, when the pollen grain of a fl owers reaches the stigma of the same, it is unable to germinate or prevented to germinate on its own stigma. Examples: *Abutilon, Passiflora*.

It is a genetic mechanism.
28. Hydrophilhy:
Pollination by water is called hydrophilhy and the flowers pollinated by water are said to be hydrophilous (Example: Vallisneria, Hydroilla). Though there are a number of aquatic plants, only in few plants pollination takes place by water. The floral envelop of hydrophilous plants are reduced or absent. In water plants like Eichhornia and water lily pollination takes place through wind or by insects. There are two types of hydrophilhy, Epiphylophilhy and Hypoaphilhy. In most of the hydrophilous flowers, the pollen grains possesses mucilage covering which protects them from wetting.

Pollination in Vallisneria spiralis: It is a dioecious, submerged and rooted hydrophyte. The female plant bears solitary flowers which rise to the surface of water level using a long coiled stalk at the time of pollination. A small cup shaped depression is formed around the female flower on the surface of the water. The male plant produces male flowers which get detached and float on the surface of the water. As soon as a male flower comes in closer to a female flower, it gets settled in the depression and contacts with the stigma thus bringing out pollination. Later the stalk of the female flower coils and brings back the flower from surface to under water where fruits are produced.

b. Hypoaphilhy: Pollination occurs inside the water. Examples: Zostera marina and Ceratophyllum.

3. Zoophily: Pollination by the agency of animals is called zoophily and flowers are said to be zoophilous. Animals that bring about pollination may be birds, bats, snails and insects. Of these, insects are well adapted to bring pollination. Larger animals like primates (lemurs), arboreal rodents, reptiles (gecko lizard and garden lizard) have also been reported as pollinators.

A. Ornithophily: Pollination by birds is called Ornithophily. Some common plants that are pollinated by birds are Erythrina, Bombax, Syzygium, Bignonia, Sterlitzia etc., Humming birds, sun birds, and honey eaters are some of the birds which regularly visit flowers and bring about pollination.

29. Events of Fertilization

The stages involved in double fertilization are:- germination of pollen to form pollen tube in the stigma; growth of pollen tube in the style; direction of pollen tube towards the micropyle of the ovule; entry of the pollen tube into one of the synergids of the embryo sac, discharge of male gametes; syngamy and triple fusion. The events from pollen deposition on the stigma to the entry of pollen tube in to the ovule is called pollen-pistil interaction. It is a dynamic process which involves recognition of pollen and to promote or inhibit its germination and growth.

Pollen on the stigma

In nature, a variety of pollens fall on the receptive stigma, but all of them do not germinate and bring out fertilization. The receptive surface of the stigma receives the pollen. If the pollen is compatible with the stigma it germinates to form a tube. This is facilitated by the stigmatic fluid in wet stigma and pellicle in dry stigma. These two also decide the incompatibility and compatibility of the pollen through recognition-rejection protein reaction between the pollen and stigma surface. Sexual incompatibility may exist between different species (interspecific) or between members of the same species (intraspecific). The latter is called self-incompatibility. The first visible change in the pollen, soon after it lands on stigma is hydration. The pollen wall proteins are released from the surface. During the germination of pollen its entire content moves into the pollen tube. The growth is restricted to the tip of the tube and all the cytoplasmic contents move to the tip region. The remaining part of the pollen tube is occupied by a vacuole which is cut off from the tip by callose plug. The extreme tip of pollen tube appears hemispherical and transparent when viewed through the microscope. This is called cap block. As soon as the cap block disappear the growth of the pollen tube stops.

Pollen tube in the style

After the germination the pollen tube enters into the style from the stigma. The growth of the pollen tube in the style depends on the type of style.

Types of style

There are three types of style a) Hollow or open style b)solid style or closed style c) semi-solid or half closed style.

Hollow style (Open style): It is common among monocots. A hollow canal running from the stigma to the base of the style is present. The canal is lined by a single layer of glandular canal cells (Transmitting tissue). They secrete mucilaginous substances. The pollen tube grows on the surface of the cells lining the stylar canal. The canal is filled with secretions which serve as nutrition for growing pollen tubes and also controlling incompatibility reaction between the style and pollen tube. The secretions contain carbohydrates, lipids and some enzymes like esterases, acid phosphatases as well as compatibility controlling proteins.

Solid style (Closed type): It is common among dicots. It is characterized by the presence of central core of elongated, highly specialised cells called transmitting tissue. This is equivalent to the lining cells of hollow style and does the same function. Its contents are also similar to the content of those cells. The pollen tube grows through the intercellular spaces of the transmitting tissue.
Semi-solid style (half closed type): This is intermediate between solid and open type. There is a difference of opinion on the nature of transmitting tissue. Some authors consider that it is found only in solid styles while others consider the lining cells of hollow style also has transmitting tissue.

Entry of pollen tube into the ovule: There are three types of pollen tube entry into the ovule(Figure 1.18).

Porogamy: when the pollen tube enters through the micropyle.

Chalazogamy: when the pollen tube enters through the chalaza.

Mesogamy: when the pollen tube enters through the integument.

Entry of pollen tube into embryo sac: Irrespective of the place of entry of pollen tube into ovule, it enters the embryo sac at the micropylar end. The pollen enters into embryo sac directly into one of the synergids. The growth of pollen tube towards the ovary, ovule and embryo sac is due to the presence of chemotropic substances. The pollen tube after travelling the whole length of the style enters into the ovary locule where it is guided towards the micropyle of the ovule by a structure called obturator (See Do you know). After reaching the embryo sac, a pore is formed in pollen tube wall at its apex or just behind the apex. The content of the pollen tube (two male gametes, vegetative nucleus and cytoplasm) are discharged into the synergids into which pollen tube enters. The pollen tube does not grow beyond it, in the embryo sac. The tube nucleus disorganizes.
